# Robust and efficient algorithms for rapid prototyping of heterogeneous objects

X.Y. Kou and S.T. Tan

Department of Mechanical Engineering, The University of Hong Kong, Hong Kong

#### **Abstract**

**Purpose** — Apart from the geometries to be dealt with, rapid prototyping (RP) of heterogeneous objects requires additional material information to be processed. This generally involves a large amount of information to be processed simultaneously. The robustness and efficiency problems, which seem less critical in homogeneous solid fabrications, become an issue. The direct impetus of this paper is to present robust and efficient algorithms for RP of heterogeneous objects.

**Design/methodology/approach** – The robustness is benefited from using the proposed non-manifold heterogeneous cellular model, which guarantees gap-free material depositions around material interfaces. The efficiency enhancement is achieved by eliminating repetitive boundary intersections and using a heuristic material interrogation approach.

**Findings** – By using the proposed algorithms, the robustness and efficiency of RP of heterogeneous objects can be improved. It is found that an average 30 percent efficiency improvement is obtained using the proposed heuristic material interrogation approach.

**Originality/value** — Non-manifold heterogeneous cell representation (HC-Rep) is used in RP fields for the first time. Based on the HC-Rep, the robustness and efficiency of RP of heterogeneous object is addressed in this paper.

Keywords Rapid prototypes, Composite materials, Physical properties of materials

#### Introduction

The term "heterogeneous objects" generally refer to objects made of different constituent materials or spatially different structures (Kou and Tan, 2007a). The need for utilizing heterogeneous objects stems from the fact that the users' functional requirements are usually multiple and conflicting, and can hardly be fulfilled by a single homogeneous material. For instance, few materials can simultaneously render high hardness and toughness, good stress shielding and biocompatibility, sufficient mechanical strength and heat resistance, etc.

By using multiple materials and properly tailoring the material heterogeneities, however, the user's multifold (sometimes contradictory) requirements can be satisfied. For instance, modern space shuttles are subjected to high temperatures (over 1,400°C; Musikant, 1991) and enormous loads. In terms of thermal resistance, ceramics are good candidate materials because of their high heat capacity and excellent corrosion resistance; however they cannot sustain strong forces. Conversely, aluminum has good strength and toughness but they fail to survive under severe temperatures (the melting point of aluminum is 660°C). A solution to surmount this is to utilize metal substrates as the skeletons and ceramic materials as coatings. Gradual material transitions from pure metals to pure ceramics can be utilized to alleviate the

Rapid Prototyping Journal 15/1 (2009) 5–18 © Emerald Group Publishing Limited [ISSN 1355-2546] [DOI 10.1108/13552540910925018] delamination problem due to the thermal expansion mismatch of ceramics and metals (Cooley, 2005), as shown in Figure 1.

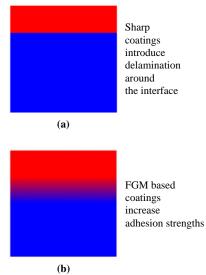

Because of many such favorable properties and unique features, *modeling* (CAD) (Adzhiev *et al.*, 2002; Bhashyam *et al.*, 2000; Biswas *et al.*, 2004; Kou and Tan, 2005; Kou *et al.*, 2006; Kumar and Dutta, 1998; Liu *et al.*, 2004; Qian and Dutta, 2003a; Xu and Shaw, 2005), *analysis* (CAE) (Kou and Tan, 2007b; Elishakoff *et al.*, 2005; Cho and Ha, 2002; Praveen and Reddy, 1998; Nemat-Alla, 2003), and *fabrication* (CAM) of heterogeneous objects have gained significant research focus in recent years.

With the recent development in solid freeform fabrication technologies, rapid prototyping (RP) methods have shown to be effective approaches for the physical realization of heterogeneous objects. Considerable research efforts (Cho et al., 2002; Khalil et al., 2004; Zhou, 2004a,b; Kou and Tan, 2006; Hu et al., 2005; Zhou et al., 2004; Tandon and Kant, 2004) have been made in the RP communities and systematic solutions are investigated. Nevertheless, many of the existing methods simply apply traditional models and algorithms which are well suited for homogeneous solid fabrications (for instance, assembly models are used to represent and fabricate multi-material objects); however significant robustness and efficiency problems arise (see the next section for details). The direct impetus of this paper is to present robust and efficient algorithms for RP of heterogeneous objects, particularly those with complex material heterogeneities. The robustness is benefited from using the proposed non-manifold heterogeneous cellular model, which warrants gap-free material depositions around

material interfaces. The efficiency enhancement is achieved by eliminating repetitive boundary intersections and using a heuristic material interrogation approach.

The remainder of this paper is logically organized as follows. Related work and the motivations of this paper are first described. The proposed data structures and algorithms are then presented; implementation details and application examples of the proposed algorithms are offered. Finally, conclusions are drawn and discussions are provided.

#### **Previous work and motivations**

### Basic algorithms for rapid prototyping of homogeneous solids

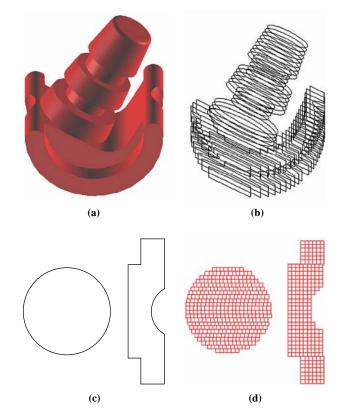

A typical flow path in RP of a homogeneous solid can be roughly described as follows:

- With a given build direction, the object geometry is first sliced by an array of parallel planes and the sectioned boundary profiles are obtained, as shown in Figure 2(a) and (b).
- For each slice, the silhouette boundary curves (Weiss *et al.*, 1997) are covered into an array of 2D regions (in Figure 2(c), two regions are covered).
- Intersect each 2D region with parallel scan lines and get a collection of 1D intervals where materials are to be deposited/solidified.
- Use the obtained data to drive the hardware setup (e.g. nozzles, lasers, etc.) to deposit/solidify materials in a voxel-wise, line-wise, and slice-wise fashion until the whole object has been thoroughly fabricated, as shown in Figure 2(d).

#### Rapid prototyping of heterogeneous object

Heterogeneous objects are generally characterized as having local material compositions (Liu et al., 2004; Cho et al., 2003; Jackson et al., 1999). In the context of layered manufacturing

Figure 2 A typical flow path in RP of a homogeneous object

**Notes:** (a) Input 3D homogeneous solid; (b) Sliced boundary curves; (c) One of the selected slices; (d) Voxelized 2D slice of the 2D region

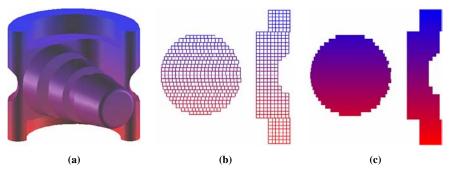

of heterogeneous objects, location dependent material data should be incorporated so that different materials can be selectively deposited/solidified at each voxel/lump (Vijay et al., 1995)

To facilitate RP of functionally graded material (FGM) objects, Siu and Tan (2002) and Zhou et al. (2004) introduced the material grading references to represent unidirectionally graded distributions. The distance from the point of interest to the reference features are regarded as the material variation variables; explicit, analytic functions were used to evaluate the local material compositions. Kou and Tan (2005) proposed a hierarchical representation to model heterogeneous objects with compound (bidirectional or trivariate) material distributions: the geometry and topology were represented with the well established B-Rep model and the material distribution was represented with "heterogeneous feature tree" (HFT) structures. To get the necessary material information required in the RP process, a recursive material evaluation algorithm was proposed (Kou and Tan, 2005; Kou, 2006). Qian and Dutta (2003a), Hua et al. (2004), and Martin and Cohen (2001) also proposed B-spine tensor product models to represent heterogeneous objects with trivariate material distributions.

Once these heterogeneous CAD models (Kou and Tan, 2007a) are constructed, the planar slicing, region covering and line scanning processes discussed in previous subsection can be similarly executed. Each voxel's material is then retrieved from the CAD model and the material with interrogated composition is deposited and solidified at each voxel, as illustrated in Figure 3.

#### Challenges and motivations

From Figures 2 and 3, it appears that if the local material compositions can be properly evaluated or interrogated, existing algorithms for RP of homogeneous solids can be almost completely immigrated to the heterogeneous object fabrications; there is no apparent significance to explicitly distinguish these two. Indeed, such an assertion is true if the objects of interest always have simple and regular material distributions as illustrated above. Here, we regard such material distributions as simple because throughout the objects' geometries, the material distribution is formulated with a single material mapping function (Kou and Tan, 2007a), no matter if it is 1D (Siu and Tan, 2002), 2D (Kou and Tan, 2005) or 3D (Qian and Dutta, 2003a) dependent on the spatial locations. More intuitively, simple material distribution can be either homogeneous, 1D or 2D graded, but not the hybrids. For general heterogeneous objects, however, it is possible that more than one generically different material distributions coexist in different portions (subdomains) of the object (Kou and Tan, 2007a; Kou et al., 2006; Cheng and Lin, 2005; Shin, 2002; Chen and Tucker, 2000). In the scenarios where the objects under fabrication have complex material heterogeneities, simply applying the above discussed algorithms may result in significant robustness and efficiency problems.

Consider the layered manufacturing of the heterogeneous object shown in Figure 4 as an example. This object is composed of five components: three homogeneous objects  $O_1$ ,  $O_3$ ,  $O_5$  and two FGM component  $O_2$  and  $O_4$ (Figure 4(b)). An intuitive and widely used approach is to represent the object with an assembly model. For instance, Langrana et al. (2000) and Weiss et al. (1997) used the assembly models (multiple standard template library (STL) files or multiple "nonlinear CAD models" (Weiss et al., 1997) to represent multi-material objects, each of which represents a homogeneous component. The benefit of using the assembly model lies in its direct intuition and easy implementation; however, if the conventional part-assembly model (Figure 4(c)) is used, then the above planar slicing algorithm will be separately applied to each of the component, O<sub>i</sub> (i = 1, 2, ..., 5), as illustrated in Figure 4(d).

Note that the face pairs  $(F_a, (F_a, F'_a))$ ,  $(F_b, (F_b, F'_b))$ ,  $(F_c, (F_c, F'_c))$ , etc. in Figure 4(c) represent exactly the same face geometry; however to get the boundary silhouette curves of each component, *identical* face-plane intersections must be *separately* applied on each face. This results in unnecessary and repetitive calculations. Similarly in the line scanning process,

identical line-edge intersections will be conducted on the edges  $e_i$  and  $e_i'$  ( $i=1,2,\ldots,5$ ), which represent the same silhouette curve, as shown in Figure 4(d). As is seen from Figures 2 and 3 that the plane-face and line-edge intersections are intensively used in the RP process, therefore these repetitive boundary-intersection computations will dramatically degrade the computation efficiencies.

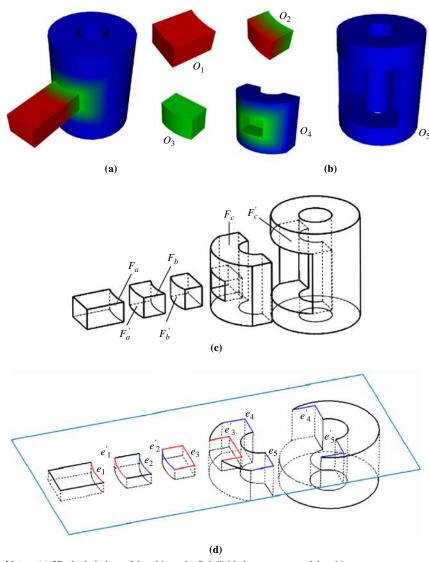

More importantly, the involved data redundancies also result in severe data consistency and robustness problems. It is well known that due to the finite hardware resolution, the staircase effect is commonplace around the object boundaries (i.e. start and end points of any scan lines). According to the algorithm presented above, the scan lines in  $\overline{P_i P_i'}$  (i =1,2,...,5) Figure 5(a) will be independently decomposed into voxels (because these voxels are generated from separate parts); therefore the staircase effect occurs around all the points  $P_i$  and  $P'_i$ . Note that in homogeneous object fabrications, such stepping effect only influences the boundary qualities or geometric accuracies, however in RP of heterogeneous objects, these staircases occur in the internal portions of the objects, resulting in either material gaps/voids or superfluous/overlapping material depositions, as demonstrated in Figure 5(b) and (c). Such fabrication flaws may accumulate line by line and layer by layer, which significantly undermine the strength of the object and ultimately, result in fabrication failures.

It can be found out that the above efficiency and robustness problems are mainly provoked due to the existence of the redundant entities such as  $F_a$ ,  $F'_a$ ,  $e_i$  and  $e'_i$ , etc. It is evident that such entities serve as the delimitation boundaries of subdomains which have different material distributions. They are introduced solely for the purpose of point containment test and material interrogations (Kou *et al.*, 2006; Qian and Dutta, 2003b). Conceptually, such material delimitation entities should not be included in the irrelevant geometric operations (such as section slicing and line scanning); instead, they should be utilized only in the material evaluation process.

Most of the existing approaches, however, either targeted for RP of objects with simple material distributions (Kou and Tan, 2006; Zhou *et al.*, 2004; Siu and Tan, 2002) or simply use the conventional models and algorithms (Langrana *et al.*, 2000) as mentioned earlier. The robustness and efficiency problems are seldom considered for objects with complex material heterogeneities. Weiss *et al.* (1997) first noted such data inconsistency problem and the possible effects of the "unpredictable and faulty" operations, however they solve the problems by manual checking to ensure reliable fabrications.

This paper provides an alternative approach to improving the robustness and efficiency of the RP of heterogeneous objects. The internal boundaries are automatically excluded from the boundary intersection and line scanning processes. A heuristic strategy is also proposed to speed up the material interrogations. The proposed methodologies are detailed as follows.

## Robust and efficient algorithms for rapid prototyping of heterogeneous objects

#### Some assumptions

In what follows, we postulate that the build direction for the RP of a heterogeneous object is a fixed or a known parameter, since the proposed algorithms can be applied to circumstances with arbitrary build directions. Without loss of generality, the positive Z direction is assumed as the default build direction. The support material deposition, material affinity/compatibility

and other problems, though equally important in practical RP fabrications, however are beyond the scope of this paper.

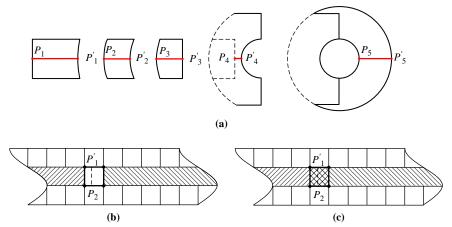

#### Heterogeneous cellular representation (HC-Rep)

To improve the robustness and efficiency, *irrelevant* boundary elements are temporarily excluded from the boundary intersection computations. Figure 6 demonstrates a desired planar slicing and line scanning configuration for the object shown in Figure 4(a). In the planar slicing process, only the boundary elements which bound the object geometries are considered as *relevant* candidates and they actually participate in the plane-face intersections; all the other internal material-delimitation boundaries are regarded as *irrelevant* entities in this stage.

To accomplish this, one needs to provide unambiguous guidelines to distinguish the *relevant* and *irrelevant* boundary elements. With the traditional part-assembly model, this is almost unattainable since all the boundary elements are

equally treated. In our previous paper (Kou et al., 2006), we have proposed a heterogeneous cellular representation (HC-Rep) to represent objects with complex material heterogeneities and this HC-Rep model can be utilized to accomplish such a task. A complete description on the HC-Rep is out of the scope of this paper and interested reader may refer to Kou et al. (2006) and Kou (2006). For brevity and self-containedness, only the most relevant parts of HC-Rep are provided here.

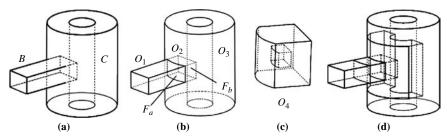

The key idea of the HC-Rep is to combine the nonmanifold cellular model (Bidarra et al., 1998; Weiler, 1986; Keen, 1993) with the HFT structure (Kou and Tan, 2005; Kou, 2006) to represent heterogeneous objects. A heterogeneous object O is represented by quasi-disjoint heterogeneous cells (Kou et al., 2006; Kou, 2006; Ferrucci, 1993). Contrary to the assembly model in which the material delimitation faces (e.g.  $F_a$  and  $F'_a$  in Figure 4(c)) are kept in separate part files, the HC-Rep maintains only one copy of such entities, as shown in Figure 7(b) and (d). Here, the cells  $O_1$  and  $O_2$  share the face  $F_a$  and cells  $O_2$  and  $O_3$  share the face  $F_b$ . These shared boundary elements are usually termed as co-boundaries. Due to the existence of such co-boundaries, the manifold conditions (i.e. "every point has a neighborhood which is homeomorphic to a two-dimensional disk" Weiler, 1988) are violated, resulting in the so-called non-manifold models (Keen, 1993). The non-manifold models can be constructed by applying the non-regularized (or standard) Boolean operations (Rossignac and Requicha, 1991).

To construct the cellular geometry in Figure 4(a), the following procedures are performed. A non-regular Boolean union is first applied on the input block B and cylinder C and the resultant object  $U_1 = \{O_1, O_2, O_3\}$  is shown in Figure 7(b). Note that the internal boundaries  $F_a$  and  $F_b$ which delimit the sub geometric domains are kept in the resultant object, rather than obligated as is done with conventional regularized Boolean operators. After the first non-union Boolean union, the connection cell O2 (Kou et al., 2006) which corresponds to the mutual lump of B and C are identified. The connection cell is then offset by a user-input distance, as shown in Figure 7(c). The purpose of this offset is to offer a smooth material transition in between the input object B and C, as shown in Figure 4(b). The ultimate cellular geometry is then obtained by performing a second nonregular union of the offset object  $O_4$  and  $U_1$ , as shown in Figure 7(d).

The material distributions of the non-manifold cells are modeled with the extended heterogeneous feature tree (eHFT) structures. The eHFT maintains the material variation dependencies among all the constructive heterogeneous features at different hierarchies. The material composition of a feature in a higher level is dependent on (or determined by) the material composition of its child features. By definition, the cells  $O_1$ ,  $O_3$ , and  $O_5$ 's material distributions (Figure 4(b)) are homogeneous (i.e. independent on other heterogeneous features Kou and Tan, 2005; Kou et al., 2006; Kou, 2006), therefore their HFTs are represented with a NULL valued tree structure,

Volume 15 · Number 1 · 2009 · 5-18

Figure 7 (a) Non-manifold cellular model construction process. (a) The input block B and cylinder C; (b) non-regular union B and C; (c) the offset of the connection cell (Kou et al., 2006) and (d) the final cellular geometry obtained by applying non-regular union of the resultant object in (b) and (c)

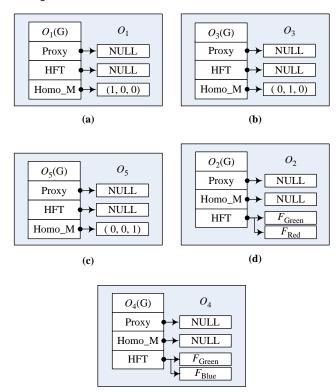

as demonstrated in Figure 8(a)-(c). The other two FGM cells  $O_2$  and  $O_4$  (Figure 4(b)) are represented with HFTs with two hierarchies: the parent level represents the cells  $O_2$  and  $O_4$ 's material distributions, the child levels are the feature nodes on which their material distributions depend, as conceptually demonstrated in Figure 8(d) and (e). Note that Figure 8 shows a simplified eHFT representation only and interested readers may refer to Kou *et al.* (2006) and Kou (2006) for the complete eHFT information and the detailed material modeling schemes.

#### Selective boundary slicing algorithm

By using the HC-Rep as described above, the unnecessary and repetitive boundary-interaction calculations can be

**Figure 8** The eHFT representations for the non-manifold heterogeneous cells

**Notes:** (a), (b), (c) are the eHFT representation for the homogeneous cells  $O_1$ ,  $O_3$  and  $O_5$ ; (d) and (e) are the eHFT representation for the FGM  $O_2$ ,  $O_4$ 

avoided and this is accomplished by use of a selective boundary slicing algorithm.

As is seen from the comparison of Figures 6(a) and 7(d), the "irrelevant" entities in the boundary intersections are the internal material delimitation boundaries, which have the characteristics of sharing themselves with other boundary elements. These *irrelevant* entities, by definition, are nothing else but the co-boundaries described earlier. Such internal boundaries can be identified and then excluded from the planar slicing and line scanning computations. The pseudo code in Figure 9 describes the selective boundary slicing algorithm.

In this algorithm, all the boundary faces are first retrieved from the non-manifold cellular models (L8 in Figure 9); relevant faces to be used in the boundary intersection are then identified and saved in the "RelevantFaceList" (L11-L15). These faces are subsequently sewn together to form a manifold solid (L17) and other remaining faces are simply neglected. A further geometry simplification is carried out to remove unnecessary edges, and adjacent faces sharing such edges are merged wherever applicable (L19).

After applying the proposed algorithm on the discussed example, the original 41 faces (Figure 4(c)) in the part-assembly model are reduced to nine faces, and a 78 percent efficiency improvement is achieved in the plane-face intersections, as shown in Table I. Note that it is the boundaries of the *manifold* solid (Figure 10(a)) that participate in the actual planar slicing (L23) and region covering (L25), as shown in Figure 10(b).

#### Efficient material interrogations

Apart from the computation overhead in geometric operations (i.e. planar slicing, line scanning, and voxelization), the material composition evaluation in RP of heterogeneous object is also a time-consuming process. For a given voxel, a brute force algorithm might be sequentially applying the point membership classification (PMC) tests on all the candidate cells until the voxel is found to be on or inside a specific cell. Once the container cell (for instance  $O_1$ - $O_5$  in Figure 8) is obtained, the voxel's material composition can be then interrogated from the corresponding HFT structures. In the worst case, all the cells will be traversed, resulting in excessively long time in material interrogation.

In this section, we present a heuristic approach to infer the possible point containment status. The idea is based on the following observations:

 For each starting voxel in a scan line, there is no indicative information as to which cell the voxel belongs, a brute force PMC test should be conducted.

**Notes:** (a) Relevant boundary elements derived by using the proposed algorithm; (b) The slicing result of applying the selective boundary slicing algorithm, a partial view

- If a voxel  $V_i$  is continuously deposited and inside the same cell  $C_{\text{buffer}}$  which contains the previously interrogated voxel  $V_{i-1}$ , then there is no need to perform the PMC test throughout the candidate cell list. Directly interrogate  $V_i$ 's material composition in  $C_{\text{buffer}}$  will do. For instance, all the voxels along the scan line  $\overline{P_{S1}P_1}$  and  $\overline{P_{S2}P_{E2}}$  are in the same cell (as indicated with the same color in Figure 11) and in these cases there is no need to perform the brute force PMC tests.
- If a voxel  $V_i$  is discontinuously deposited, i.e. there are holes/gaps between  $V_{i-1}$  and  $V_i$  (for instance, the voxels at  $P_{E1}$  and  $P_{S2}$  in Figure 11), then there is no guarantee that these two voxels will be in the same cell, a brute force PMC test should be applied.
- The continuous or discontinuous status of two voxels can be judged by their x (line scanning direction) coordinate discrepancies, if it is bigger than the voxel's resolution,

Figure 11 PMC test using the internal material delimitation boundaries

Volume 15 · Number 1 · 2009 · 5-18

then these two voxels are discontinuously deposited (e.g. the voxels at  $P_{E1}$  and  $P_{S2}$ ).

- To tell whether two voxels V<sub>i-1</sub> and V<sub>i</sub> are in the same cell, one can judge from their x (line scanning direction) coordinates. If V<sub>i</sub> is located on the left side of the intersection point (e.g. P<sub>1</sub>) of the scan line with the internal material delimitation boundary (e.g. F<sub>A</sub> in Figure 11), then the current voxel V<sub>i</sub> is in the same cell as V<sub>i-1</sub>. Only when V<sub>i</sub>'s x coordinate is bigger than P<sub>1</sub>'s, do they fall inside different cells.
- The material delimitation points (e.g. P<sub>1</sub>) can be obtained from the intersection of a ray (along the scan line direction) with the internal faces.

Based on the above observations, we can minimize the bruteforce PMC tests through a heuristic approach. The pseudo code shown in Figure 12 describes the detailed algorithm. In this algorithm, the cell which contains the last interrogated voxel  $V_{i-1}$  is explicitly kept in a buffer pBufferCell, see L8 in Figure 12. A scan line (e.g. the colored center line in Figure 13(a)) is first intersected with all the *internal* material delimitation boundaries (the black hidden lines in Figure 13(a)), see L10 in Figure 12 (note that the *internal* material delimitation boundaries can be identified with a similar algorithm as the one shown in Figure 9). All the x coordinates of the intersection points  $P_{\rm int} = \{P_1, P_2, P_3\}$  are then sorted in an ascending order and kept in a list KeyInterPos (L11 and L13).

For each voxel  $V_i$  under interrogation, we check if  $V_i$  is located on the left side of the head element of intersection points list  $P_{\text{int}}$  (L21). If the result is confirmative (for instance, the voxel  $V_1$ ,  $V_{k-1}$ , and  $V_k$  in Figure 13(a) are on the left side of  $P_1$ ), then it can be confirmed that the current voxel  $V_i$  and the previously interrogated voxel  $V_{i-1}$  are in the same

Figure 13 A heuristic approach for efficient material interrogations

**Notes:** (a) Scan line subdivisions based on the internal material delimitation boundaries; (b) Voxels to be interrogated with the brute force PMC tests, highlighted with colors; grey voxel indicate voxels interrogated with the proposed heuristic approach; (c) Evaluated material compositions, a wire frame view; (d) Evaluated material compositions, a shaded view

heterogeneous cell, therefore there is no need to test  $V_i$ 's containment throughout all the candidate cells. In this scenario, one can directly interrogate  $V_i$ 's material composition from pBufferCell's HFT structure (L28), where the pBufferCell holds the cell which contains the previously interrogated voxel  $V_{i-1}$ . In the other case when  $V_i$ is located on the right side of the head element of  $P_{\text{int}}$  (for example, the voxel  $V_{k+1}$  in Figure 13(a) has gone across  $P_1$ ), then voxel  $V_{k+1}$  and  $V_k$  are in different cells, a brute force PMC test needs to be applied on  $V_i$  (L24 and L28) to interrogate the voxel's containment; to implement this, pBufferCell is assigned a NULL pointer to indicate that no previous cells are available as the "shortcut" candidate containers. After the brute force PMC tests on  $V_{k+1}$ , the pBufferCell is updated with  $O_2$  which contains the just interrogated voxel  $V_{k+1}$ , as shown in L28 in Figure 12 and Table II. Moreover, the KeyInterPos is also updated by removing the head element from the list (L23, Figure 12), for instance,  $P_1$ 's x coordinate is removed and the intersection point list turns to be  $P_{\text{int}} = \{P_2, P_3\}$  after  $V_{k+1}$  is traversed, as shown in Table II. For the next voxel along the scan line, which is  $V_{k+2}$ , the same check of its location with respect the head element of  $P_{\text{int}}$  (which is now  $P_2$ ) is similar conducted, and the above heuristic PMC test continues.

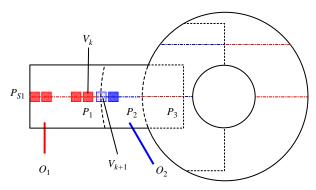

By keep tracking of pBufferCell and the list KeyInterPos in such a manner, the brute force PMC tests are performed on limited voxels only, as highlighted with colored voxels in Figure 13(b). All the remaining voxels (grey colors in Figure 13(b)) are freed from the time-consuming PMC tests, and the materials are directly evaluated from pBufferCell's HFT structure. In the above discussed example, all the HFT structures are shown in Figure 8.

Table II The status of some key variables during the heuristic PMC tests

| $V_k$                       | <i>O</i> <sub>1</sub>        | <i>O</i> <sub>1</sub>       | $P_{\text{int}} = \{P_1, P_2, P_3\}$        |  |  |  |  |  |
| $V_{k+1}$                   | NULL                         | $O_2$                       | $P_{\text{int}} = \{P_2, P_3\}$             |  |  |  |  |  |
| $V_{k+2}$                   | $O_2$                        | $O_2$                       | $P_{\text{int}} = \{P_2, P_3\}$             |  |  |  |  |  |

It should be noted that Figure 13(a) only demonstrated an ideal case where a voxel is precisely located on the left or right side of the intersection points  $P_i$ . Due to the finite voxel resolutions, it is common that the  $P_i$  falls within a voxel, as shown in Figure 14. Under such circumstances, we use the center location of the voxels to compare with the intersection point  $P_i$ . Depending on different material query strategies, such voxels' material composition may be evaluated from one of the HFT structures of the adjacent cells (e.g.  $O_1$  and  $O_2$  in Figure 14). Also note that such inexact material compositions only result in the so-called "material accuracy" (Kou, 2006) problems, however the materials are still consecutively deposited/solidified, and this is essentially different from the stair case effect depicted in Figure 5(b) and (c). As such, the proposed scheme can still ascertain the gap-free material

Figure 14 The material accuracy related to the voxel resolutions

depositions in heterogeneous object fabrications and there is no strength loss arisen from the proposed algorithms.

The results of the proposed heuristic material evaluation algorithm are demonstrated in Figure 13(c), (d) and 15. Quantitative time consumptions of the brute force algorithm and the proposed heuristic approach are provided in Table III. For each fabrication resolution, three tests are conducted and the average time is used in evaluation of the efficiency improvement.

#### Implementations and examples

#### **Implementations**

The proposed algorithm has been successfully implemented in CAD4D (Kou and Tan, 2004) – a standalone heterogeneous object modeler developed by the authors at Department of Mechanical Engineering, The University of Hong Kong. CAD4D is based on the commercial geometric modeling kernel ACIS (www.spatial.com/products/acis.html) and the eHFT representations (Kou *et al.*, 2006; Kou, 2006). Microsoft foundation class libraries are utilized to implement the graphic user interface; C++ STL is used to implement container related data structures and algorithms; and OpenGL is used as the rendering engine for object visualizations.

A snapshot of CAD4D package is shown in Figure 16. Due to the literal inadequacy of a word written paper, we also provide three flash animations to demonstrate:

- 1 the HC-Rep model construction process;
- 2 application of the presented selective boundary intersection algorithm; and
- 3 application of the heuristic material evaluation algorithm.

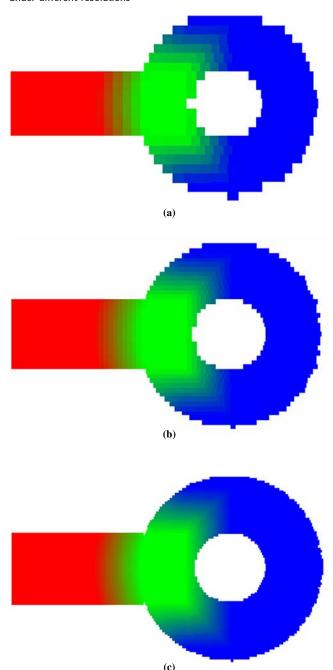

These flash animations facilitate the readers to better understand the proposed scheme and are available for downloads at the authors' webpage http://web.hku.hk/  $\sim$  kouxy/CAD4D/CAM4D/.

#### **Examples**

In this section, we present several examples to demonstrate the application of the proposed scheme. Figure 17 shows the simulated RP of a heterogeneous propeller. The application of the selective boundary intersection algorithm is demonstrated in Figure 17(d), (g), and (j). The original 65 faces to be intersected (Figure 17(a)/(b)) are reduced to 14 faces after applying the proposed algorithm, and the 2D silhouettes (Figure 17(d), (g), and (j)) are therefore efficiently computed without unnecessary and repetitive plane-face intersections.

**Figure 15** The material evaluation results for a heterogeneous layer under different resolutions

**Notes:** (a) a resolution of 2mm; (b) a resolution of 1mm; (c) a resolution of 0.5 mm

The evaluated material compositions of these 2D layers are shown in Figure 17(e), (f), (h), (i), (l), and (k). In the presented examples, an average 30 percent efficiency improvement is obtained using the proposed heuristic material interrogation approach.

To test and validate the proposed selective boundary intersection algorithm, we also fabricated a few prototypes using Z Corporation's 3D printer (www.zcorp.com/). The heterogeneous CAD models containing both the geometric

Figure 16 A snapshot of CAD4D graphic user interface

and material information are converted to VRML files with the CAD4D package. The generated VRML files contain only the boundary faces which are actually involved in the planar slicing processes. These VRML files are submitted to the 3D printer for physical fabrication. For the readers' interest, several such VRML files are also available for downloads in our web site. Some fabricated examples are shown in Figure 18(a) and (c). Notice that these prototypes show the object's external material distributions only. To demonstrate their internal material distributions, we also fabricated a few sliced prototypes, as shown in Figure 18(b) and (d).

#### **Conclusions and discussions**

RP of heterogeneous objects has received considerable research interest in recent years. Many existing methods simply reuse traditional solid models/algorithms and loosely attach the heterogeneous material distributions to the object geometries. At the cost of the legacy compatibility and easy implementation, significant robustness and efficiency problems arise.

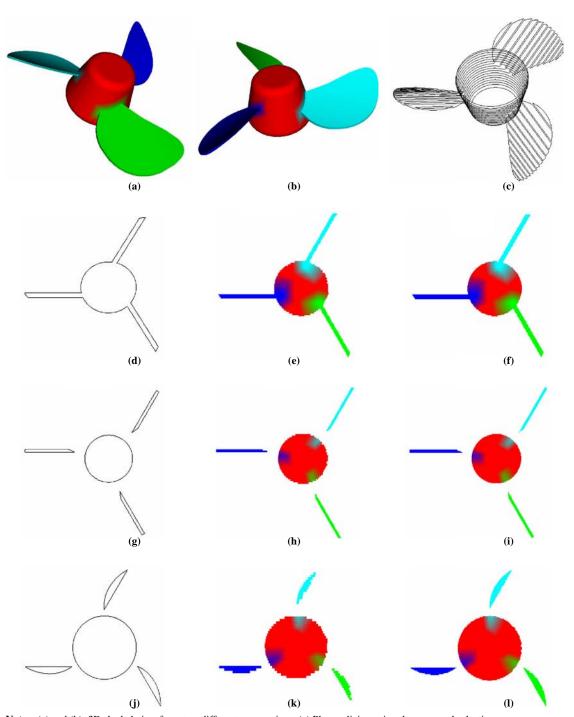

This paper presents robust and efficient algorithms for RP of heterogeneous objects. A HC-Rep is used to model objects with complex material heterogeneities. Instead of simply using

all the geometric boundaries in the planar slicing and material interrogation processes, the proposed scheme selectively choose the relevant entities in corresponding computations. A selective boundary intersection algorithm is proposed to eliminate repetitive boundary intersections. The efficiency of the planar slicing is significantly improved and gap-free material depositions around material interfaces are guaranteed. A heuristic material interrogation approach is also proposed to speed up the material evaluation process; brute force PMCs are carried out on limited voxels only. Software simulations and physical fabrication experiments show that the proposed approach can effectively improve the robustness and efficiency of RP of heterogeneous objects.

Due to the limited space, the construction of cellular geometric models is not fully elucidated as it involves the use of Radial-Edge structure (Weiler, 1988) and *non-regular* Boolean operations (Kou *et al.*, 2006; Rossignac and Requicha, 1991). Interested readers may find off-the-shelf implementations in the ACIS (www.spatial.com/components/) library. The complex heterogeneity modeling problem is not fully explained in this paper either, which is a new hotspot in heterogeneous object modeling and applications. The readers may refer to the recent review paper (Kou and Tan, 2007a) for more details on the existing modeling paradigms.
